Abstract

1
2 We examine the results of the Aqua Planet Experiment project focusing
3 mainly on the structure of equatorial precipitation in the subset of partic-
4 ipating models on which details of model variables are available. In spite
5 of the unified set-up of APE, the Hovmöller plots of the precipitation in
6 the models exhibit wide range of diversity, presumably resulting from the
7 diversity among implementations of various physical processes in partici-
8 pating models. Still, the wavenumber frequency spectra of precipitation
9 exhibit certain degree of similarity; the power spectra can be divided into
10 Kelvin mode, westward inertio gravity mode, and “advective” component.
11 The intensity of each of the three components vary significantly in differ-
12 ent models. The sum of the variance of the three components reflects, to
13 certain extent, the amount of precipitation on the equator in each of the
14 models, but relative contribution of each components differ among the mod-
15 els. Composite spatial structure of the above three components are made by
16 the space-time filtering to separate each of the three spectral components
17 and performing regression analysis. The composite horizontal structures of
18 Kelvin and westward inertio gravity components in the models are similar
19 to each others and resemble to those expected from corresponding shallow
20 water equatorial wave modes, but the similarity degrades at the levels where
21 the phase velocity is near the zonal mean zonal wind. The horizontal struc-

1 tures of “advective” components diverge significantly among models. The
2 composite vertical structures for all of the three components are found to
3 be strongly model dependent. Based on the comparison among vertical and
4 horizontal structure of convective and stratiform heating in the composite
5 disturbances, the diversity of vertical structure originates from the differ-
6 ence in physical processes, implementation of cumulus parameterization in
7 particular.

1. Introduction

Convective activity in the earth's tropical atmosphere is recognized to exhibit a hierarchical structure including individual cumulonimbi, mesoscale features, cloud clusters (Houze and Betts 1981), various kinds of synoptic scale disturbances such as convectively coupled equatorial waves (Kiladis et al. 2009), intraseasonal variability (ISV) (Madden and Julian 1972), and climatological features like intertropical convergence zone (ITCZ) or convection centers. Each of the classes in the hierarchy has unique importance, for example in the role in the maintenance of the climate system (Sherwood et al. 2010), predictability of the numerical weather prediction, or severe meteorological phenomena central to the disaster prevention. Thus, the reproduction and the understanding of the hierarchy is one of the most important theme of tropical meteorology.

There remains a large degree of difficulty in our efforts to capture the hierarchical structure. The most obvious difficulty is its extremely wide range of spatial and temporal scales; there is four orders of magnitude difference from the smallest member, individual cumulonimbi having 1–10 km scale, to the largest member, ISV and ITCZ, which have a global scale. If we wish to simulate whole of the hierarchical structure explicitly, we have to run a global cumulus resolving model; its execution requires huge computational resource (Tao and Moncrieff 2009). Up to present, only a very limited

1 number of such explicit calculations are accomplished (Satoh et al. 2008).
2 Other than such explicit simulations, any kinds of global modeling is, to
3 more or less degree, compromised to incorporate the effect of the smaller
4 classes of the hierarchy, i.e., cumulonimbi and mesoscale systems. The most
5 common way of the compromise has been to employ cumulus parameter-
6 ization, although there are a few exceptional attempts to avoid cumulus
7 parameterization by using “distorted” dynamical equations (Kuang et al.
8 2005).

9 It is true that computational resources are rapidly developing, some de-
10 gree of cumulus parameterization is considered to remain in global models at
11 least for long term runs for the projection of possible global warming. There-
12 fore, the knowledge on the performance of the numerical models employing
13 cumulus parameterizations in the reproduction of tropical convection hier-
14 archy remains important in some unforeseeable period in the future. At
15 present, there are not small number of cumulus parameterization used in
16 operational or community atmospheric models including adjustment type
17 schemes (Manabe et al. 1965), mass flux schemes (Tiedtke 1989), and the
18 schemes employing ensemble of cumulus (Arakawa and Schubert 1974). In
19 spite that each of the numerical models are highly tuned to reproduce the
20 behavior of the real atmosphere when used in the atmospheric models, it has
21 been known that properties of tropical atmospheric convection in numerical

1 models exhibit wide variety, and it is still agreed that no single model can
2 be nominated as the one that reproduce the reality. We have to examine
3 how and why various models behave differently by comparing the results of
4 such models in a common setup in inter comparison comparison projects
5 such as AMIP or CMIP.

6 Aqua-planet experiment project (APE) is an attempt to compare the be-
7 havior of modern sophisticated numerical models used for numerical weather
8 prediction or climate simulations in the simplest set-up of the “aqua planet”,
9 i.e. a virtual planet wholly covered with ocean of fixed surface temperature.
10 The context and aim of the APE is fully discussed in Blackburn and Hoskins
11 (2011), where the history and the position of idealized AGCM experiments
12 in the framework of atmospheric research in general is also stated. The
13 setup of aqua-planet was first employed purposefully by Hayashi and Sumi
14 (1986) in order to find the “natural” behavior of tropical atmospheric con-
15 vection with a successfully identifying the hierarchy, or its substitutes in
16 low resolution model employing cumulus parameterization, suggesting cloud
17 clusters, super cloud clusters, ISV, tropical cyclones and double ITCZ. One
18 may regard this setup is trivial or easy one because it is free from com-
19 plex treatment of land surface and associated hydrology and/or vegetation
20 schemes. Still, it presents a unique and difficult challenge to AGCMs; being
21 free from the external forcing provided from the inhomogeneity of underly-

1 ing surface, the model atmosphere have to determine its behavior by itself,
2 so that both of the strength and the weakness of each numerical models
3 would be exposed clearly. In fact, as early as at the begging of 1990's, it
4 has been clarified the choice of cumulus parameterization strongly affects
5 several fundamental properties of AGCM such as the behaviors of tropi-
6 cal disturbances (Numaguti and Hayashi 1991a) or the structure of ITCZ
7 (Numaguti and Hayashi 1991b).

8 The present paper describes the behavior of equatorial precipitation
9 structure in CONTROL experiments conducted in APE project. Among the
10 series of classes of the hierarchical structure of tropical precipitation convec-
11 tion, we will focus our attention to the “intermediate” scale structure, i.e.,
12 convectively coupled equatorial waves (Kiladis et al. 2009), because of the
13 following reasons in particular. First, which is the most trivial reason, the
14 smaller classes, individual cumulonimbi and mesoscale systems are below
15 the resolvable scales of most of the AGCMs participating the APE project.
16 Second, which is also trivial, the larger classes, ISV and larger scale, are
17 presumably strongly affected by the present idealized, unrealistic setup of
18 aqua planet, so that the behavior of the models are not expected to be
19 tuned well. It is also possible that mechanism governing ISV in the present
20 setup is different from the ISV in the real atmosphere, so that these fea-
21 tures should be examined from a wider perspective elsewhere. Third, which

1 is the most important, is that, as will be shown later, the behavior of con-
2 vectively coupled waves in the models in APE displays rich variety possibly
3 depending on the choice of cumulus parameterization employed. The exam-
4 ination of variety of the properties of CCEWs in APE should enhance our
5 knowledge on the underlying mechanism governing the CCEWs in coarse
6 resolution AGCMs, which would lead us to the guiding principles on how
7 to tune cumulus parameterization so as to better represent the behavior of
8 the real atmosphere.

9 The paper is organized as follows. Section 2 will explain the setup of
10 experiment. Because details of the APE project is given elsewhere (Black-
11 burn and Hoskins,2011), only brief summary will be presented. Section 3
12 will present the method of analysis. Section 4 will compare gross feature
13 of CCEWs in APE models. Section 5 will compare the composite struc-
14 ture of three categories of CCEWs produced from the regression analysis
15 of spectrally filtered time series from several selected models participating
16 the APE project. Discussions and conclusions will be given in the last two
17 sections.

18 **2. Setup of Experiments**

19 The experiments to be examined in this paper is the CONTROL case
20 of the APE project. For the details not touched here, readers are referred

1 to the context paper (Blackburn and Hoskins 2011) or the original pro-
2 posal paper (Neale and Hoskins 2000). The SST distribution is zonally
3 uniform and fixed in time. The meridional structure is shown in Fig. 1.
4 The SST profile is characterized with a rather sharp single peak located at
5 the equator and north-south symmetric. The latitudinal gradient is steep
6 from subtropics to midlatitude, whereas it flattens in high latitude region.
7 Reflecting this character, climatological subtropical and mid-latitude jets
8 effectively merge to form a single very strong jet located in subtropics.

9 In the APE project archive, the results of 17 AGCM runs from 15 groups
10 are accumulated. A brief summary of the specification of the models is given
11 in Table 1. Among these, 7 groups provided more detailed time series on
12 additional model variables for 8 runs, from which we obtain composite struc-
13 ture as presented later. It is worth mentioned that even the subgroup on
14 which composite analysis is made contains wide variety of spatial resolution
15 and cumulus parameterizations employed. More complete specifications are
16 given in the APE-ATLAS (Williamson et al. 2011) to which readers are
17 referred to.

Table 1

Fig. 1

1 **3. Methods of analysis**

2 *3.1 Data*

3 The primary data used in this study are the 6-hourly one year time
4 series (“TR”) of CONTROL experiments. We also analyze the “additional
5 transient time series” containing multilevel model variables in 7 AGCM
6 runs conducted in the APE project, which are AGUforAPE, CSIRO_std,
7 ECMWF05, ECMWF07, GSFC, LASG, NCAR. In the present paper, we
8 mainly examine on the latter data. The former contains model variables
9 on very limited model levels, and are only consulted in order to check the
10 representativeness of the 7 model runs focused in this study among all of the
11 AGCM runs. The variable we examined are eastward wind, northward wind,
12 vertical velocity, temperature, geopotential height, specific humidity, and,
13 precipitation flux. In addition, temperature tendency due to parameterized
14 convective process and that due to resolved condensation are used in the
15 composite analysis of disturbances. Note that the temperature tendency
16 terms are not provided for CSIRO_std, and LASG does not provide the
17 tendency due to resolved scale condensation.

3.2 *Hovmöller plots and wavenumber frequency spectra*

In section 4, we show plots of time evolution (“Hovmöller” plots) and wavenumber frequency power spectra of precipitation along the equator. The former is produced simply by extracting the precipitation on the equator; for the models that do not have grid points on the equator, the data at the grid points in southern hemisphere nearest to the equator is used instead. The wavenumber frequency spectra are made by the following procedures. (i) From the original 1-year time series of each model run, ten 90-day time series are made which begin at every 30 days from the beginning. (ii) From each of the 90-day segment, linear trend, which is estimated using least square fit, is subtracted. (iii) Double Fourier transform is executed to obtain the space time power spectrum of each of the segments. (iv) All of the space time power spectra of the ten 90-day segments are averaged to obtain the final estimates of the wavenumber frequency power spectrum of the precipitation in the model.

In addition to the wavenumber frequency power spectra, we present the “enhanced” power spectra of the meridionally symmetric component of precipitation within 5 degree latitudes. The methods to obtain the enhanced spectra basically follows that used in Wheeler and Kiladis (1999). (i) The time series of north-south symmetric component of precipitation is made at each latitudes. (ii) The wavenumber frequency power spectra of the above

1 time series is made in the same procedure as explained in the previous
2 paragraph for the power spectra at the equator. (iii) Thus obtained power
3 spectra at all latitudes within 5 degree from the equator are averaged. (iv)
4 The above spectra are divided by their “background” spectra, which are
5 obtained by applying 1-2-1 smoothing in wavenumber and frequency 40
6 times.

7 *3.3 Wave-type filtering*

8 In section 5, we examine the structure of disturbances associated with
9 the precipitation at the equator separating the types of the convectively
10 coupled equatorial disturbances. The method of separation basically fol-
11 lows that in Wheeler et al (2000). We focus on three types of convectively
12 coupled equatorial disturbances, which are Kelvin ($n=-1$) mode, westward
13 inertio gravity ($n=1$) mode, and “advective” component. (Hereafter these
14 three components are referred to as K mode, WIG mode, and AD com-
15 ponents, respectively.) The last one has been referred to as “TD-type”
16 component in Wheeler and Kiladis (1999). However, the ITCZ appear-
17 ing in the CONTROL experiment in most models are sharply concentrated
18 at the equator (Blackburn et al. 2011a), so that the disturbance in the
19 wavenumber frequency domain of the traditionally called “TD-type” do not
20 necessarily accompany vorticity which is an important character of con-

1 ventional tropical depressions, so that we choose the name of “advective
2 component” instead.

3 The procedure to isolate each of the three types of components again
4 basically follows that of Wheeler et al (2000). (i) We perform double Fourier
5 transformation of the three dimensional time series of the variables to be
6 analyzed in longitude and time. (ii) We filter the wavenumber frequency
7 spectral coefficients that passes each of the wavenumber frequency domains
8 that characterize the three types of disturbances, whose specifications are
9 described below. (iii) We perform inverse double Fourier transformation
10 of the filtered wavenumber frequency to obtain the three dimensional time
11 series of variables representing each of the three types of disturbances. The
12 definitions of the filters for the three disturbance types are shown in Fig. 2.
13 The range of equivalent depth associated with the K filter is broader than
14 that in Wheeler and Kiladis (1999). where the range between 8m and 50m
15 is employed. By the present choice, we intend to cover the wide variety of
16 Kelvin wave type disturbances appearing in the APE experiments. In each
17 of the experiments, however, the range of the equivalent depth of dominant
18 Kelvin component is much narrower, as will be presented later.

1 3.4 Composite structure

2 In Section 5, we present composite structure of K, WIG, and AD com-
3 ponents along equator appearing in each of the seven AGCM runs. The
4 composite structure is obtained by performing (simultaneous) regression
5 analysis of the time series of model variables filtered through one of K,
6 WIG or AD filter. Thanks to the idealized zonally symmetric configuration
7 of the CONTROL experiment of APE, the procedure of regression is quite
8 simple. We extract a time series of a filtered model variable (*predictand*) at
9 a height and a latitude, and shift the extracted data longitudinally by a cer-
10 tain zonal length, and calculate the slope of linear regression of the shifted
11 time-longitude data against filtered precipitation at the equator. For models
12 that does not have grid points at the equator, the average of the precipita-
13 tion along the two latitudes are used instead. By repeating this procedure
14 for all latitude, height, and zonal shift length, we can obtain the composite
15 three-dimensional structure of the model variable for the disturbance of the
16 filter used. We will not perform the lagged regression analysis, but averaged
17 temporal evolution of the disturbance is, to some extent, expected to rep-
18 resented as the zonal structure of the composite disturbance. The detail of
19 the temporal evolution may be of interest, but it is left for future research.

20 It should be bear in mind that the magnitude of the regression slope
21 of a particular variable at certain position for a particular model does not

1 necessarily represent the intensity of the model variable actually realized
2 in the model; it depends on the intensity of the filtered rainrate along the
3 equator realized in the model, which varies significantly on different models
4 as will be shown shortly below. The units of the regression slope are the
5 units of the predictand per unit rainrate. However, for convenience, we
6 multiply the values of the regression slope by a normalization intensity of
7 precipitation, which is $0.0001 [kg \cdot s^{-1} \cdot m^{-2}]$, and represent all predictand
8 with their original units.

Fig. 2

9 **4. Behavior of equatorial precipitation in APE mod-** 10 **els**

11 *4.1 Hovmöller plot of equatorial precipitation*

Fig. 3

12 Temporal evolution of precipitation at the equator of each model is
13 shown in Fig. 3, where one can find quite a wide range of variety among the
14 hierarchical structure of precipitation in different model runs. The structure
15 seem to depends equally on the parameterizations of physical processes and
16 on the spatial resolution. For example, higher resolution models such as
17 DWD, ECMWF, FRCFC, CSISRO represents fine spatial structure, which
18 lacks in lower resolution models, such as AGUforAPE, CGAM etc. On the
19 other hand, the behavior of ECMWF_05 and ECMWF_07, which has the

Fig. 4

Fig. 5

1 same resolution and slightly different cumulus parameterization, differ con-
2 siderably. The variety represented by all APE models is so widespread that
3 is difficult to describe meaningfully how one model differs from another. So
4 we only point out several noteworthy features.

5 In some models, eastward propagating planetary scale signals, whose
6 propagation speed is not very different from ISV in the real atmosphere
7 (Madden and Julian 1994), are notable with different intensity. FRCGC,
8 i.e., NICAM run shows most prominent eastward propagating signal as was
9 described in Miura et al (2005) and Nasuno et al (2008). It is also evi-
10 dent in the results of K1Japan, two versions of UKMO, and two versions of
11 ECMWF, but the intensity or detailed structure differ considerably. On the
12 other hand, such eastward propagating low wavenumber signal is weak or
13 absent in AGUforAPE, NCAR, and CISRO-old. In spite that these models
14 are common in lacking notable eastward propagating signal, they differ sig-
15 nificantly; the precipitation in NCAR is generally weak and rather uniform,
16 whereas that in CISRO-old is generally intense, and that in AGUforAPE
17 are organized in westward propagating structure.

18 If we focus on smaller scale structure, as a common feature, precipitation
19 occurs near the “grid scale”, i.e. nearly smallest scale resolvable in all
20 models, but the behavior of the grid scale precipitation varies significantly.
21 The life time of such grid-scale precipitation varies among models ranging

1 from about one day to nearly ten days. Moreover the direction of migration
2 of those gridscale precipitation structure also differ among models: those in
3 AGUforAPE and MIT move generally westward, those in ECMWF-05 and
4 GFDL are nearly stationary, and those in UKMO, K1JAPAN, ECMWF-07,
5 DWD, and CSIRO move generally eastward.

6 *4.2 Space time spectra of precipitation*

7 In contrast to the extremely rich variety in the appearance of equatorial
8 precipitation in longitude time plot, the wavenumber-frequency spectra of
9 the equatorial precipitation of 17 model runs (Fig. 4) exhibit some degree
10 of similarity. The most common feature is the eastward propagating signal.
11 In most model, the dominant power of the eastward propagating signal
12 is distributed mainly along respective dispersion relation of Kelvin mode,
13 although the intensity, characteristic equivalent depth, and, dominant zonal
14 wavenumber differ among the models. The identification of these signal
15 as the Kelvin mode is supported by the composite analysis of its spatial
16 structure, which will be shown later.

17 The eastward propagating signal in NCAR is, however, somewhat differ-
18 ent from those in other models; the dominant wavenumber, 5–10, is much
19 larger than that in other models, 1–5. Moreover, the strong power seems
20 to be distributed along the dispersion curve of $n=1$ eastward propagat-

1 ing inertio gravity wave (EIG). Strangely, the wavenumber-frequency spec-
2 trum of mid-tropospheric vertical velocity (not shown) exhibits much weaker
3 wavenumber dependence, so that the ratio of the intensity of precipitation
4 to the intensity of vertical velocity, which might be interpreted as the gross
5 sensitivity of the response of the latent heating to the grid scale ascent,
6 strongly depends on the wavenumber; precipitation is much more sensitive
7 to vertical velocity in zonal wavenumber 5–10 than in zonal wavenumber
8 1–5. In the results of other models, there are not such distinct variation
9 of the sensitivity, and their magnitude are more or less similar to that for
10 the wavenumber 5–10 in NCAR. It should be also noted that the reduced
11 “sensitivity” of precipitation to the vertical velocity in NCAR is observed
12 only near the equator. This latitudinal dependence may be related to the
13 latitudinal profile of ITCZ; NCAR is characterized with distinct “double
14 ITCZ” structure, but most of other models in APE is characterized with
15 “single ITCZ”. These evidence suggest that the eastward propagating signal
16 in NCAR bear some character of eastward propagating inertio gravity wave
17 with equivalent depth is about 12 m. However, as will be shown later, its
18 structure is not very different from that of Kelvin wave.

19 In contrast to the more or less common emergence of Kelvin signal,
20 the intensity and the spreadings of “background component” vary much
21 more drastically among the models. They reflect both the climatological

1 structure of ITCZ and the structure of precipitation events. As is described
2 in Blackburn et al (2011a) the mean precipitation intensity at the equator
3 varies over a factor of 3 among the models, and, as will be shown in the
4 next section, the model with larger mean precipitation intensity exhibits
5 the larger power of over-all variance of precipitation. The frequency and
6 wavenumber bandwidths are, from the definition of the Fourier components,
7 related to the degree of concentration of precipitation in the real space. More
8 widespread background component found in DWD, ECMWF05, LASG, and
9 NICAM reflect more concentrated grid-scale precipitation structure noted
10 in fig. 3. It is interesting that, in most models, westward component extends
11 to higher frequency than eastward component does, although the reasons
12 are unclear.

13 More intricate features are more easily seen in fig. 5, which are produced
14 after the signal enhancing technique of Wheeler and Kiladis (1999). The
15 westward propagating background component, are, in some models, divided
16 into the component along the dispersion curve of westward propagating in-
17 ertio gravity wave and component of lower frequency. The former will be
18 called “inertio gravity wave’, or WIG, component, following the notation
19 used for observed OLR in Weeler and Kiladis (1999). The latter com-
20 ponents will be called “advective” components because they are generally
21 distributed about straight lines passing through the origin in the frequency

1 wavenumber space, so that the motion appear to result from the advection
2 caused by certain easterly wind, although the actual relationship between
3 the propagation speed of the advective components and the zonal wind is
4 not straight forward as will be discussed later.

5 The behavior of WIG signals exhibits significant variety among models,
6 although to smaller degree than for the advective components. In AGU-
7 forAPE and CGAM, the WIG signal is very weak, while it is distinct in
8 LASG and K1JAPAN. Not only the intensity but also the distribution over
9 the wavenumber-frequency space varies: the signal covers a wide range of
10 wavenumber in LASG and K1JAPAN, but only higher wavenumber com-
11 ponent can be noted in GSFC. It is worth noting that there is a gradual
12 change of the characteristic equivalent depth of WIG as wavenumber varies:
13 the WIG of larger scale has the shallower equivalent depth. The most clear
14 example is that in LASG. This tendency may suggest that the strength of
15 the coupling between the modelled convective heating and the large scale
16 convergence associated with the WIG depends on the wave period resulting
17 in the varying degree of “reduced stability” effect discussed by Gill (1982).

18 Because of the clean setup of the aqua planet experiment project, one
19 can also note several types of planetary scale disturbances. other than the
20 convectively coupled equatorial waves and advective signals. One is the
21 quasi-stationary wavenumber five signal. Most prominent example can be

1 found in the result of NCAR. Together with ten-day period wavenumber six
2 component nearby, it seems to be associated with the midlatitude baroclin-
3 ically unstable waves like those examined by Zappa et al (2011). Another
4 type of examples are the diurnal and semi-diurnal migrating tides (Wool-
5 nough et al. 2004). Additionally, several types of normal mode waves, which
6 are the 33-h Kelvin wave (Matthews and Madden 2000), the mixed-Rossby
7 gravity mode, $n = 0$, and Rossby modes, $n > 1$, (Hendon and Wheeler
8 2008) for their counterparts in the real atmosphere, can be found. These
9 features are only marginally identifiable in the space-time spectra of precip-
10 itation, but are more easily confirmed in the spectra of zonal wind or surface
11 pressure (not shown here). Among these waves, the representation of the
12 33-h Kelvin wave is found to be sensitive to the vertical resolution and/or
13 upper boundary conditions of the models, although other type of planetary
14 scale disturbances mentioned above are more insensitive. The description
15 of those waves is left for future research.

16 In many experiments, the tidal signal modulates the tropical precipita-
17 tion associated with the Kelvin or advective signals significantly. Such mod-
18 ulation results in high frequency, low wavenumber component that some-
19 times overlaps the frequency-wavenumber domain of WIG and/or EIG(Eastward
20 propagating Inertio Gravity wave). Most clear example is the branch going
21 through (wavenumber,frequency) $=(-5,0.9)$ and $(-10,0.6)$ in the spectra of

1 UKMO (fig. 5(p,q)).

2 **5. Spectral filtering analysis**

3 As described in the previous section, there are prominent variety in the
4 space-time structure of equatorial precipitation in APE models. It is highly
5 probable that various different choice of discretization schemes, spatial reso-
6 lution, and parameterizations of physical processes among the models result
7 in the variety of model behavior. However, it is quite difficult task to point
8 out one or more items that cause one or more particular difference of behav-
9 ior. Before any progress be made, it is necessary to describe the difference
10 of model behavior.

11 As an attempt to systematically describe the varying behavior of equa-
12 torial precipitation in the APE models, we separate the model variables
13 into the contributions of Kelvin, WIG, and advective components, then
14 construct composite structure of them for each model, and compare the
15 character of each composite waves in various models.

16 The experiments to be analyzed are CONTROL cases done by the subset
17 of APE models, of which the detailed transient datasets are submitted,
18 which are AGUforAPE, CSIRO, ECMWF-05, ECMWF-07, GSFC, LASG,
19 and NCAR. In spite that the spectral property of each component differ
20 among models, we use the same definition for the filters to extract each of

1 the three spectral components, which are shown in Fig. 2. As a result, some
2 part of the dominant spectral power is excluded from the composite in some
3 models, the most significant of which is the low wavenumber part of the WIG
4 in LASG. By this choice, we prioritize the uniformity of filters applied to
5 the results in all of the models to be compared than the completeness of
6 coverage of the three spectral components appearing in the models.

7 *5.1 Intensity of Kelvin, gravity and advective components*

Fig. 6

Fig. 7

8 Before examining the spatial structure of each components, we compare
9 their intensity in the APE models. Fig. 6(a) shows the variance of equatorial
10 precipitation calculated from the time series that are filtered by K, WIG,
11 and AD filters in the seven APE models. It is found that the intensity of
12 all components are strongly model dependent. LASG and ECMWF05 are
13 members that exhibit strongest disturbances, whereas NCAR, GSFC, and
14 CSIRO are those with weakest. All of the Kelvin, gravity, and advective
15 components summed up, the intensity in ECMWF05 is about 6 times as
16 large as that in NCAR. The significant difference of intensity of disturbance
17 in the model can be mostly explained by the difference of rainfall intensity
18 at the equator. Fig. 7 is the scatter plot showing the relationship between
19 squared time mean zonal mean precipitation intensity at the equator and
20 the overall intensity of disturbance, which is defined as the sum of the three

1 components. Total variance, i.e., the variance of unfiltered precipitation at
2 the equator, are also plotted for the corresponding model. We can find that
3 both the overall disturbance intensity and the total variance are well corre-
4 lated to the average precipitation intensity squared. There are two outliers;
5 LASG exhibits larger variance, whereas CISRO exhibits smaller variance.
6 Lastly, we examine the relative contribution of the three disturbance com-
7 ponents to the variance of precipitation. Fig. 6(b) compares the variance of
8 Kelvin wave, gravity wave, and advective components scaled by the total
9 variance in each of the models. Two aspects can be commonly noted for all
10 of the models; the sum of the three components contributes about half or
11 larger part of the total variance, and the gravity wave component is weak-
12 est in the three kind of disturbances. However, the relative contributions of
13 Kelvin wave and advective components varies largely. There is weak nega-
14 tive correlation between the intensities of Kelvin wave and advective com-
15 ponents. AGUforAPE and ECMWF07 show contrasting feature; advective
16 components dominates in AGUforAPE, whereas Kelvin wave dominates in
17 ECMWF07. How the contributions of the three components are determined
18 in each model is very important issue. We next examine the structure of
19 the Kelvin wave, gravity wave, and advective components appearing in each
20 of the model in the next subsection, hoping that the analysis may provide
21 clues to the above mentioned issue.

5.2 Composite structure of Convectively Coupled Equatorial

Waves

Hereafter, composite structure of Kelvin wave, westward gravity wave, and advective component filtered structure of the seven APE models. As was written in section 3, the composite structure is derived from the regression of corresponding filtered variables to the symmetric component of filtered precipitation intensity at the equator. The variables in the following figures are scaled for $0.0001[Kg/s \cdot m^2]$ precipitation anomaly at the reference latitude, 180 degree longitude, so that the intensity of composite disturbance presented in the following figures do not represent the intensity of those disturbance emerging in the models; only the structure matters.

a. Kelvin filtered component

Composite Kelvin wave mode is presented in Fig. 8–14. Fig. 8 shows the horizontal structure of precipitation and horizontal wind on 925hPa for the K filtered composite. In all models, the precipitation anomaly is well confined near the equator. However, the latitudinal extent somewhat differ; They are sharply confined to the equator in EC05 and LASG, whereas they are broad in AGU, EC07, and NCAR. Generally, the north-south extent correspond to the width of the ITCZ in each model (Williamson et al. 2011). The longitudinal structure also differ among the models; it is confined in

Fig. 8

Fig. 9

Fig. 10

Fig. 11

Fig. 12

Fig. 13

Fig. 14

1 LASG and EC05 and GSFC, and is broader in AGU and EC07. In NCAR,
2 the precipitation anomaly has a wave-like variation with the wavelength
3 of 2500–3000km, and associated with off-equatorial component which is
4 delayed with 10 degrees. Similar off-equatorial component can be found
5 also in GSFC. Note that both of the two models are characterized with
6 distinct double ITCZ structure (Williamson et al. 2011). The horizontal
7 wind structures deviate from that expected from the shallow water Kelvin
8 wave (Matsuno 1966) with different degrees; commonly found feature is
9 meridional convergence. It typically occurs at almost the same location
10 of the zonal convergence. The intensity of the meridional flow is not very
11 different from that of the zonal flow.

12 Fig. 9 shows the horizontal structure of geopotential and horizontal wind
13 on 850hPa surface for the Kelvin wave component. We can observe that,
14 in most of the models, the horizontal structure of the disturbance is similar
15 to that of shallow water equatorial Kelvin wave (Matsuno 1966) the geopo-
16 tential and zonal wind perturbations are positively correlated and confined
17 within several degrees from the equator. Zonal component dominates in the
18 wind field near the equator, converging around the location 5-10 degrees to
19 the east of the maximum precipitation anomaly. As a feature that devi-
20 ate from the structure of classical shallow water Kelvin wave, we can note
21 the significant meridional wind perturbation near the precipitation maxima.

1 However, the strength of the meridional wind perturbation depends on the
2 choice of variable for the key used to the regression; composite horizontal
3 structure based on the regression to low level zonal wind at the equator
4 (not shown here) exhibits much weaker meridional wind, displaying larger
5 degree of similarity to the shallow water Kelvin wave.

6 An apparent exception is AGUforAPE. Around the location of the max-
7 imum precipitation anomaly, the the zonal wind perturbation is strongly
8 confined in the vicinity of the equator. One can notice cyclonic curvature
9 of the wind perturbation around 5 degree latitude, which suggests the pos-
10 sible existence of weak Rossby response. It is noted that, the meridional
11 wind perturbation converging around the maximum of precipitation seems
12 to be originating in higher latitude, where we can find a pair of geopoten-
13 tial perturbation, positive to the west and negative to the west, that is,
14 in geostrophy, consistent with the equatorward converging meridional wind
15 perturbation. The Kelvin wave filtered correlation coefficient of the sub-
16 tropical geopotential perturbation to the equatorial precipitation exceeds
17 0.15 around the longitude of precipitation maximum, suggesting possible
18 existence of forcing from, or interaction with mid-latitude.

19 By more careful inspection, we can find that NCAR is another excep-
20 tion. First, while there is only one pair of high and low pressure anomaly
21 along the equator in other models, two or more pairs can be clearly noted

1 in NCAR. This feature is consistent with the character of the power spec-
2 tra of equatorial precipitation; wavenumber 7–10 component is dominant
3 in NCAR (Fig. 4(o)), whereas smaller wavenumber component is dominant
4 in other models. Second, the precipitation anomaly exhibits a significant
5 meridional phase difference; the zonal maxima in the latitude of the ITCZ
6 is located at about 10 degree to the west of that at the equator. This horse-
7 shoe like structure is also interpreted as the superposition of the equatorial
8 Kelvin wave and the eastward inertio gravity wave, the latter being shifted
9 by about 5 degrees to the east of the former. This interpretation is not in-
10 consistent with the structure of low level horizontal wind that deviates from
11 that of pure Kelvin wave. As noted earlier, in NCAR, the eastward prop-
12 agating precipitation signal in the frequency wavenumber space (Fig. 3(o))
13 seems to be dominated along the dispersion relation of the eastward inertio
14 gravity wave having the equivalent depth of about 10 m. These two evidence
15 suggests that, the eastward propagating equatorial precipitation structure
16 in NCAR includes, in addition to the conventional equatorial Kelvin wave
17 structure, some contribution of eastward propagating inertio gravity wave.

18 In contrast to the above mentioned similarity in the low level struc-
19 ture, considerable model dependence can be found in the upper tropospheric
20 structure. Fig. 10 shows the horizontal structure of geopotential and hori-
21 zontal wind on 250hPa surface for the Kelvin wave component. Divergence

1 of zonal wind perturbation around maxima of precipitation, which is ex-
2 pected for Kelvin-like disturbance, is found only for LASG and NCAR. In
3 ECMWF07 and GSFC, the area of zonal wind convergence is found far
4 to the east of the precipitation maximum. In AGUforAPE, CSIRO, and,
5 ECMWF05, zonal wind is convergent at the precipitation maxima; the hor-
6 izontal divergence that is required as the continuation of the upward flow
7 at the precipitation maxima is accounted exclusively by the divergence of
8 meridional flow. Additionally, significant vortical perturbations are notable
9 in the subtropics, although the phase of the vortices relative to the location
10 of the precipitation maxima varies among the models. These diversity of
11 upper troposphere appear because the phase velocity of the Kelvin wave
12 like perturbation, which is typically $10 \sim 30$ m/s, is not very different from
13 the zonal mean zonal wind in the upper troposphere in the tropical to sub-
14 tropical latitude in the models, so that Rossby wave like response can be
15 resonantly excited, and the structure of the response could be sensitive to
16 the subtle difference of the structure of basic state and the heating in the
17 precipitation anomaly.

18 Fig. 11 shows the vertical structure of temperature, zonal wind, and ver-
19 tical velocity along the equator for the Kelvin wave component. The vertical
20 structure of the Kelvin mode appearing in models displays a wide variety.
21 We can notice at least four types of temperature perturbation among the

1 composite structure in the models. i.e., the first baroclinic mode signal
2 extending whole depth of troposphere, the second baroclinic mode signal
3 which has two maxima of amplitude in the troposphere that are somewhat
4 out-of-phase to each other, the shallow signal at around 600hPa that are pre-
5 sumably associated with the melting of ice phase hydrometeor, and another
6 shallow signal near the surface possibly associated with the evaporation of
7 raindrops. In each of the models, the four types of temperature signal ap-
8 pear in different combination, intensity, and phase relationship, resulting in
9 the wide variety of the temperature structure.

10 Fig. 12 shows the vertical structure of specific humidity, zonal wind, and
11 vertical velocity along the equator for the Kelvin wave component. As a
12 common feature, in most models, the humidity field is characterized with
13 a “slant” structure; lower troposphere is moist to the east of the rainfall
14 anomaly, and dry to the west, whereas middle and upper troposphere is
15 dry to the east and moist to the west. In GSFC, however, east-west con-
16 trast of the humidity is in opposite sign to that in the other models. An-
17 other common feature is shallow dry region near the surface to the west of
18 the precipitation anomaly, which presumably results from (parameterized)
19 evaporation of raindrops.

20 Structure of circulation on the equator, which is shown in Fig. 11 and
21 Fig. 12, considerably vary among the models. In majority of the models,

1 first baroclinic mode structure dominates in the vertical velocity, although
2 the location of upward motion does not necessarily corresponds to the area
3 of upper level zonal divergence because of the significant contribution of
4 meridional divergence as will be shown later. However, some degree of west-
5 ward tilt, or some contribution of the second baroclinic mode, can also be
6 noted in most models. Clearest examples are found in ECMWF07, LASG,
7 and NCAR. The composite disturbance in GSFC has one notable feature; a
8 significant cool downward flow in the lower troposphere, which is somewhat
9 similar to the mesoscale downward flows that develop below anvil clouds
10 associated with mesoscale precipitation features (Houze and Betts 1981), is
11 found to the west of the maximum of precipitation in GSFC. However, its
12 zonal extent is too broad to be regarded as mesoscale; this feature could be
13 explained as a cumulative effect of more compact cold downdraft found in
14 the advective mode, which will be presented later.

15 The composite structure of temperature tendencies due to parameter-
16 ized convection, DTCONV, and that due to resolved clouds, DTCLD, on
17 the equator are shown in Fig. 13 and Fig. 14, respectively. In all models,
18 DTCONV is zonally well confined. In NCAR significant negative value is
19 observed to the west and east of the precipitation anomaly, but, considering
20 that the precipitation itself has a zonally wavy structure (Fig. 13(e)), it cor-
21 responds directly to the in situ precipitation. On the other hand, vertical

1 structure of DTCONV strongly model dependent. In LASG, it is distributed
2 mainly in the lower troposphere. In AGUforAPE, EC05, and, EC07, it is
3 mostly confined above the freezing level, whereas in GSFC, NCAR, it has
4 a deep structure extending both lower and upper troposphere. In EC07,
5 there is a region of cooling near the surface, presumably resulting from
6 parameterized rain evaporation.

7 The structure of DTCLD is strongly model dependent, not only in its
8 vertical structure but also in its zonal structure. In AGUforAPE and EC05,
9 DTCLD is zonally confined and its vertical structure is similar to that of
10 DTCONV in the corresponding model. In EC07, GSFC, and presumably
11 NCAR, DTCLD extends much more extensively in zonal direction than the
12 precipitation. In EC07 and GSFC, the vertical structure has the second
13 baroclinic mode feature; the heating in the lower troposphere is positive to
14 the east and negative to the west of the updraft, nicely representing the
15 cooling due to evaporation of stratiform precipitation. It should be noted
16 that the cooling area extends about 3000 km to the west of the updraft,
17 which is much wider than the typical extent of “mesoscale precipitation
18 features” (Houze and Betts 1981). As a result, overall structure of the
19 heating is somewhat similar to “giant squall lines” observed in the upward
20 motion area of Madden Julian Oscillation as described e.g. in Mapes et
21 al (Mapes et al. 2006). There is also a shallow region of cooling near the

1 surface in EC05, EC07 and NCAR. Such cooling near the surface is absent
2 in AGUforAPE.

3 In summary, the composite structure of Kelvin filtered component has
4 some degree of similarity to Kelvin waves discussed previously in many
5 aspects. It is especially true for the horizontal structure in the lower tro-
6 posphere. The vertical structure is shown to be strongly model dependent,
7 and the intensity of the Kelvin component disturbance in particular model
8 seems to be correlated with how much the composite disturbance is similar
9 to the unstable modes of wave-CISK. It should bear in mind, however, that
10 the vertical structure of the heating is, in most models, far from zonally
11 uniform, so that wave-CISK in its classical sense (Hayashi 1970), where
12 cumulus heating is assumed to be proportional to the vertical velocity at the
13 top of the boundary layer with fixed vertical profile, does not apply to the
14 composite Kelvin filtered disturbances as it is.

15 *b. Westward propagating gravity wave filtered component*

16 Composite gravity wave mode is presented in Fig. 15–21. Fig. 15 shows
17 the horizontal structure of precipitation and horizontal wind on 925hPa
18 surface for the WIG component. Fig. 16 shows the horizontal structure of
19 geopotential and horizontal wind on 850hPa surface for the gravity wave
20 component. We can observe that the horizontal structure of the pressure

Fig. 15

Fig. 16

Fig. 17

Fig. 18

Fig. 19

Fig. 20

Fig. 21

1 and wind disturbance is similar to that of shallow water westward propagat-
2 ing equatorial gravity wave. For all model, there is clear dipole of geopoten-
3 tial signal aligned on the equator, and the regions of horizontal convergence
4 and rainfall, which is about equally contributed by zonal and meridional
5 convergence, exist to the west of the positive geopotential anomaly. In
6 AGUforAPE and LASG, the rainfall represents wavy variation. It should
7 be mentioned that the low level convergence is preceding the precipitation
8 maximum by about 5 degrees. The structure in the upper troposphere
9 (Fig. 17) is, unlike for the composite of Kelvin wave component, similar to
10 that of that of shallow water westward propagating equatorial gravity wave.
11 The signature of the each variable is contrary to that of the corresponding
12 variable in the low level except that whole of the structure is shifted to
13 the east; the area of the horizontal divergence is located to the east of the
14 precipitation maxima by 5 – 10 degrees, being consistent with the eastward
15 tilt of the vertical velocity anomaly shown later. The smaller degree of
16 the model dependence of the upper tropospheric horizontal structure of the
17 gravity wave component compared to that of the Kelvin wave component
18 can be understood if we keep the direction of the two disturbance compo-
19 nents in mind; the gravity wave component propagates westward so that
20 Doppler shifted phase velocity in the troposphere is not small in anywhere
21 in the troposphere, but it becomes small in the upper troposphere for the

1 Kelvin component as mentioned previously.

2 Fig. 18 shows the vertical structure of temperature superposed on zonal
3 wind and vertical velocity along the equator for the WIG component. Fig. 19
4 is but for specific humidity. Like for the Kelvin wave component they dis-
5 play a wide variety. Shallow signal at the melting level and near the surface
6 are notable. Other temperature features seems to be more complex than
7 often found first or second baroclinic mode structure. A pair of temperature
8 dipole in the lower troposphere in GSFC, warm to the west and cool to the
9 east of the precipitation maxima, is one of such examples. The intensity
10 of temperature anomaly, vertical velocity, and specific humidity is large in
11 GSFC, LASG, where the activity of WIG is significant. Vertical velocity
12 signal has some eastward tilt in many of the models, being in consistent with
13 wave-CISK theory. The west-moist east-dry signal in the lower troposphere
14 in CSIRO, EC05, EC07 are more evident those for the Kelvin component
15 (Fig. 12) zonally reversed. In GSFC, as for K, the humidity signal tilts back-
16 ward. In GSFC and NCAR, east-west contrast of humidity near the surface
17 is notable. In EC05, where strong WIG activity exists, the intensity of the
18 disturbance seems to be rather weak. However, as noted earlier, the plotted
19 quantities are the coefficients of regression to the unit amount of precipita-
20 tion, so that, in EC05 that has quite large amplitude of WIG component
21 of precipitation, the amplitude of WIG component actually emerging in the

1 model is quite significant.

2 The composite structure of temperature tendencies due to parameter-
3 ized convection, DTCONV, and that due to resolved clouds, DTCLD, on
4 the equator are shown in Fig. 20 and Fig. 21, respectively. The structure
5 of DTCONV in each model is generally similar to that in the composite
6 of Kelvin component in the corresponding model. If we compare care-
7 fully, however, the vertical distribution of the heating is shifted a bit to the
8 lower altitudes than for the Kelvin filtered component in all models. The
9 structure of DTCLD is also generally similar to that in the composite of
10 Kelvin component in the corresponding model, except that the zonal direc-
11 tion is reversed and the zonal extent is shortened to about one-third. The
12 structure of DTCLD for WIG in NCAR seems to be considerably different
13 from that for K. However, considering more solitary distribution of rain-
14 fall in WIG composite and more wavy one in K composite, the structure
15 for WIG should be more directly represent the DTCLD associated with a
16 single rainfall event. Indeed, the west-moist east-dry structure in WIG can
17 easily understood as representation of shallow cloud activity preceding the
18 updraft and the evaporation of stratiform-type rainfall.

19 In summary, the composite structure of WIG filtered component has
20 a character of the westward propagating inertio gravity waves. In parallel
21 with Kelvin component, the vertical structure of composite disturbances,

1 having tilted updrafts and temperature field in some models, is similar to
2 the unstable mode of wave-CISK. The same caution on the applicability
3 of the classical wave-CISK theory also applies to WIG filtered composite
4 disturbance. In particular, the WIG disturbance in GSFC, being associated
5 with cold downward motion region in the lower troposphere that should gen-
6 erate kinetic energy, is considerable deviation from the simple wave-CISK
7 that primarily focus on the effect of (positive) condensation in convective
8 clouds.

9 *c. Advective component*

Fig. 22

10 Fig. 22 shows the horizontal structure of precipitation and horizontal
11 wind on 925hPa for the AD filtered composite. In all models, the pre-
12 cipitation anomaly is confined both meridionally and longitudinally. The
13 zonal extent is much smaller than those for K or WIG components, There
14 is negative anomaly to the east and west of the main positive anomaly
15 in EC05 and LASG. In NCAR, there are two area of negative anomaly
16 in off-equator. The horizontal wind anomaly differ among the models as
17 is in those on 850hPa surface shown below. Fig. 23 shows the horizontal
18 structure of geopotential and horizontal wind on 850hPa surface for the
19 advective component. Reflecting the significant diversity found in the lower
20 level structure in various models described above, the horizontal structure

Fig. 23

Fig. 24

Fig. 25

Fig. 26

Fig. 27

Fig. 28

1 of low level signal is also strongly model dependent. In AGUforAPE, there
2 is a pair of cyclone straddling the equator at the location of maximum pre-
3 cipitation. More or less similar pair of cyclones can be noted also in CSIRO,
4 but they are located nearer to the equator. In ECMWF05, there is a low
5 pressure anomaly on the equator at the maxima of precipitation, but, in
6 contrast to the vorticity dominated flow in AGUforAPE, the low level flow
7 converges directly without appreciable curvature. In ECMWF07, the low
8 level signal is weak and anticyclonic. In GSFC, the maxima of precipita-
9 tion accompanies distinct high pressure anomaly and divergence, and the
10 flow to the east exhibits anticyclonic circulation. In LASG, a low pressure
11 area on the equator is located at the precipitation maxima, and convergent
12 flow is observed just to the west. The signal is weak in NCAR. In contrast
13 to the diversity in the low level described above, the signal in the upper
14 troposphere (Fig. 24) in all of the model are similar to each other, being
15 characterized with a compact high pressure anomaly from which horizontal
16 wind diverges almost isotropically.

17 Fig. 25 shows the vertical structure of temperature, zonal wind, and ver-
18 tical velocity along the equator for the advective component. Fig. 26 shows
19 but for humidity anomaly. The structure of the signal is extremely model
20 dependent. ECMWF05 is characterized with a deep warm core through
21 which an upright ascending motion exists. AGUforAPE is unique in the

1 presence of a intense low level warm anomaly. These two are common in
2 lacking the cool anomaly near the surface that are seen in most of the other
3 models; a lower tropospheric warm core exists also in CSIRO, but it ex-
4 hibits a distinct surface cold signal. ECMWF07, GSFC, and NCAR are
5 common in that lower troposphere below the melting level $\sim 600\text{hPa}$ is
6 cool, and EC07 has a distinct cool region near the surface. Characteristics
7 of lower tropospheric vertical velocity varies even in the three models; up-
8 draft dominates in EC07, but it is almost absent in NCAR, and further,
9 downward motion dominates in GSFC. LASG exhibits a cold anomaly in
10 the low level, a warm anomaly around 500hPa , and a cold anomaly near the
11 tropopause; shallow cold anomaly that is found in other models, presumably
12 associated with the parameterized melting of icy hydrometeors, is absent.
13 Humidity structure is characterized with zonally confined positive anomaly
14 at the location of precipitation, but its vertical structure is model depen-
15 dent. In AGUforAPE and LASG, the updraft is wholly covered by deep
16 moist anomaly. Middle to upper troposphere is moist at the precipitation
17 anomaly also in other models, but lower tropospheric humidity structure is
18 model dependent.

19 The composite structure of temperature tendencies due to parameter-
20 ized convection, DTCONV, and that due to resolved clouds, DTCLD, on
21 the equator are shown in Fig. 27 and Fig. 28, respectively. The structure

1 of DTCONV in each model is generally similar to that in the composite of
2 K or WIG component in the corresponding model. If we compare carefully,
3 however, the vertical distribution of the heating is shifted a bit to the higher
4 altitudes than for the K or WIG filtered component in all models. This dif-
5 ference is most notable in NCAR and GSFC. In most models, DTCLD is
6 zonally localized in contrast with the zonally extended distribution realized
7 in K and WIG filtered composite (Fig. 14 for K and Fig. 21 for WIG). GSFC
8 is an exception in that weak sign-reversed component is distributed to the
9 east of the precipitation area. As in K and WIG, the vertical structure of
10 DTCLW are similar to that of DTCONV in AGUforAPE and EC05. In
11 other three models, EC07, GSFC, and, NCAR, lower troposphere is the
12 region of cooling. These cooling, which results presumably from the evap-
13 oration of stratiform cooling, nearly cancels the heating due to convection
14 (DTCONV) in these models. The cancellation is consistent with the weak
15 updraft in the lower troposphere in these models.

16 In spite of the widely different structure among the models described
17 above, we can point out two common features shared in all models; the
18 vertical motions are upright, and are localized around the precipitation
19 maxima. These two points are in contrast with the structure of composite
20 signals found for the Kelvin and gravity wave filtered data, both of which
21 have significant tilting and broader zonal extent. The upright structure

1 of the advective component suggest that it is not wave-CISK but CIFK
2 (conditional instability of the first kind) that drives AD component.

3 **6. Discussions**

4 *6.1 Possible mechanism supporting each type of disturbances*

5 We try to point out possible mechanism that governs the intensity of
6 each filtered component in different models.

7 *a. Kelvin mode*

8 In models with intense Kelvin disturbance, i.e., EC05, EC07 and LASG,
9 (Fig. 4(g)and(l)) the vertical structure of the composite disturbance (Fig. 11(d)and(f))
10 are similar to the (eastward propagating) unstable modes of wave-CISK
11 (e.g., Hayashi, (1970); Lau and Peng, (1987); Chang and Lim, (1988)) and
12 the observed convectively coupled Kelvin wave (Wheeler and Kiladis 1999);
13 both temperature perturbation and vertical velocity are tilted westward,
14 and the two variables are positively correlated in the upper troposphere,
15 which accounts the conversion from available potential energy to kinetic en-
16 ergy. It may also be noted that the appearance of Kelvin mode commonly
17 appears irrespective of the diversity of upper level structure (Fig. 10). This
18 may suggests that the process in the lower level, where the horizontal struc-
19 ture is fairly common in all models (Fig. 8 and Fig. 9).), is crucial to the

1 excitation of disturbance, not in contradiction to wave-CISK framework in
2 a loose sense stressing the importance of the coupling between convective
3 activity and low level upward motion. It should be stressed that, as was
4 mentioned earlier, vertical structure of heating in each model is confirmed
5 to evolve following the wave phase mainly due to the contribution from (pa-
6 rameterized) stratiform cloud process (Fig. 14); wave-CISK in its original
7 form is not valid in such cases.

8 In other models, updraft and/or temperature anomaly lacks proper ver-
9 tical tilt. In CSIRO, updraft is slightly tilted westward, but temperature
10 anomaly is not tilted, and it is tilted eastward in GSFC. In AGUforAPE,
11 only the second baroclinic mode is significant in the temperature anomaly,
12 and the negative correlation of upward motion and temperature in the lower
13 troposphere is unfavorable for the generation of kinetic energy. NCAR
14 seems to be an exception; the temperature anomaly has insignificant tilt
15 (Fig. 11(g)) in spite that Kelvin component is fairly dominant in the relative
16 disturbance intensity (Fig. 6(b)). This strange behavior could be related to
17 its possible connection with $n=1$ EIG mentioned in Section 4 and/or the
18 off-equatorial structure, both of which await further study.

19 In order to explain the fact that eastward propagating signal emerge,
20 albeit weak, in CSIRO, GSFC, AGUforAPE, and NCAR, mechanism(s)
21 other than classical wave-CISK may be required. One possibility is the

1 wind-induced surface heat exchange (Emanuel 1987). Another is the forcing
2 from, or the interaction with midlatitude. Supplementary analysis of the
3 model variables in Kelvin component filtered data shows that non negligible
4 correlation exists between the midlatitude meridional wind and the low
5 latitude precipitation in these models, which may support the relationship
6 between the two latitudinal bands. Some authors, for example, Zappa et
7 al (2011) and Straus and Lindzen (2000), suggest the possibility of such
8 interaction, The confirmation of such mechanism in APE data is left for
9 future research.

10 *b. Gravity wave component*

11 Compared to the case of the Kelvin wave diturbances above, the rela-
12 tionship between the structure of disturbance and the intensity of the distur-
13 bance in different models is less clear. In the absolute intensity, the gravity
14 wave signal is most intense in ECMWF05 and LASG (Fig. 4(f)and(l)). In
15 these models, temperature disturbance has eastward phase tilt, which is a
16 feature common to an (westward propagating) unstable mode of wave-CISK.
17 Similar tilted structure can be noted for NCAR and ECMWF07 (Fig. 18(d)
18 and (g)), where gravity wave disturbance is not strong. Somewhat stronger
19 warm first baroclinic mode signal may be a factor enhancing wave-CISK in
20 ECMWF05. Measured by the intensity of gravity wave component relative

1 to the total variance (Fig. 6(b)), LASG and GSFC are the models with
2 relatively intense gravity wave component. A common features notable in
3 the gravity wave structure in these two models are strong temperature and
4 vertical velocity perturbations in the lower troposphere (Fig. 18(e) and (f)),
5 This combination may be preferable to activate the coupling between the
6 gravity wave and convective activity. In GSFC, downward flow in the cool
7 anomaly in the lower troposphere to the east of the precipitation anomaly,
8 which contributes to the release of available potential energy, may be helping
9 the appearance of relatively significant gravity wave component. This cool
10 downdraft is presumably induced by the cooling due to the (parameterized)
11 evaporation of stratiform rain (Fig. 21). Its timescale (1day) and horizontal
12 extent (1000km) are not very different from those of observed mesoscale
13 precipitation systems (Houze and Betts 1981) and WIG (Takayabu 1994b),
14 or so-called “2-day waves” (Haertel and Kiladis 2004), although whether
15 such seemingly superficial correspondence supports particular parameteri-
16 zation of cloud process or not is unclear.

17 *c. Advective component*

18 Advective component is significant in ECMWF05, LASG, and AGU-
19 forAPE, measured either by absolute intensity or by its contribution to
20 total precipitation variance (Fig. 6(a) and 6(b)). Before examining factors

1 that make the “advective” components in these three models intense, it is
2 important to examine whether the “AD” components in these models should
3 be identified as advective component in more strict sense, whose phase ve-
4 locity is close to the low level zonal wind near the equator (Wheeler and
5 Kiladis 1999). In the frequency wavenumber spectra (Fig. 4 or 5), we can
6 easily find the AD components in AGUforAPE and LASG have their dom-
7 inant phase velocity, while we can not for ECMWF05; the AD component
8 spectrum of ECMWF05 is scattered in a wide range with “red” frequency
9 distribution in wavenumber-frequency space. Because of this wide band-
10 width, significant portion of power does fall within the defined spectral re-
11 gion of the AD component also in EC05, but it is simply spreading broadly,
12 so that no characteristic velocity can be pointed out. In AGUforAPE and
13 LASG, the dominant westward phase velocity is about 10.3m/s and 7.7
14 m/s, respectively, which is reasonably close to the zonal mean zonal wind
15 at 850hPa in the corresponding model, which is 11.2 m/s and 8.3 m/s, re-
16 spectively; Hovmöller plot for LASG (Fig. 3(1)) may display an impression
17 with much faster phase velocity, but it results from the superposition with
18 faster propagating westward inertio gravity mode. The coincidence of the
19 zonal wind velocity and the phase speed of AD mode suggests that the
20 motion of AD mode is indeed governed by advection of certain physical
21 variables in LASG and AGUforAPE; they are surely “advective” compo-

1 ment. On the other hand, EC05 requires more careful examination. In the
2 Hovmöller plot of precipitation (Fig. 3(f)), we notice that typical grid-scale
3 convection in ECMWF05 is not short-lived; they sometimes last for as long
4 as about 5 days. Looking into such cases closely, we can find that the grid-
5 scale convection moves only very slowly; in some cases it does not move at
6 all throughout the 5 day lifetime. This slow movement is not trivial be-
7 cause it can hardly be explained by advection of physical variables by the
8 zonal mean zonal wind, which is -7.5 m/s at 850 hpa. More careful examina-
9 tion, however, assures us that they are indeed “advective” feature. Because
10 the location of strong grid-scale convections are, in EC05, typically to the
11 west of the zonal convergent area of the Kelvin wave, so that the westerly
12 wind anomaly at those locations almost completely offsets the zonal mean
13 easterly.

14 Another issue to be examined is what the physical quantity that keeps
15 the identity of AD component is (are). In AGUforAPE, it seems to be
16 the water vapor mixing ratio, which exhibits a deep positive anomaly at
17 the maxima of precipitation (Fig. 26(a)). The low level vorticity anomaly
18 at the off equatorial portion of the precipitation anomaly (Fig. 23(a)) may
19 contribute to keep the identity of AD component disturbance to some ex-
20 tent. At the same time, the absence of surface cold anomaly, which is one
21 of the unique characters of the composite structure of AD component in

1 AGUforAPE, is favorable to the longevity of convective activity observed in
2 the Hovmöller plot (Fig. 3(a)). In LASG positive moisture anomaly at the
3 rainfall maxima is also found (Fig. 26(f)), but we are less confident on the
4 feasibility of the moisture anomaly as the mechanism serving as the memory
5 variables to be advected, because the low level cold anomaly (Fig. 25) may
6 prevent persistent convective activity as is discussed below.

7 If we compare the composite vertical structures in the models with sig-
8 nificant AD components, namely ECMWF05 and AGUforAPE, with those
9 in the models with weaker AD components (Fig. 25 and 26), we come to
10 the idea that cold anomaly in the lower troposphere, whether thick (NCAR,
11 ECMWF07, GSFC) or shallow (GSIRO), suppresses the development of the
12 AD component. In other words, we can observe that the AD component or
13 grid scale precipitation is strong and long-lasting when the composite struc-
14 ture of AD component exhibits warm lower troposphere. One extreme case
15 is AGUforAPE, where the full depth of lower troposphere is warm and moist
16 (Fig. 25(a) and 26(a)), Possible factor that contributes to the establishment
17 of the warm core is ineffective evaporation of raindrops in these two models
18 as are suggested in the composite temperature tendency (Fig. 27(a,b) and
19 28(a,b)).

20 The absence of rain evaporation is favorable not only for the development
21 of “grid scale convection” by CIFK but also for the maintenance of such

1 disturbance (Nakajima and Matsuno 1988). The other extreme is GSFC,
2 where the evaporation of rain in the lower troposphere seems to be very
3 strong. As shown in Fig. 4(j), AD component is very weak whereas gravity
4 mode is significant instead. The existence of the deep moist core found
5 in AGUforAPE and ECMWF05 (Fig. 26(a)and(c), respectively) may look
6 inconsistent with the ineffective rain evaporation, but one should recognize
7 that the evaporation of rain cools the atmosphere and induce downward
8 motion, which contributes to drying of the atmosphere. Such significant
9 sensitivity of the behavior of grid scale convection to the rain evaporation
10 is demonstrated by the contrast between the behavior of AD components
11 in ECMWF05 and ECMWF07; from the former to the latter, parameteri-
12 zation of rain evaporation are revised so as to increase the efficiency of rain
13 evaporation (Bechtold et al. 2008). It is interesting to note that, the revi-
14 sion results in the enhancement of Kelvin wave signal, although the reason
15 remain unclear.

16 *6.2 Comparison with observed Convectively Coupled Equato-* 17 *rial Waves*

18 It would be useful to compare the behavior of the CCEWs simulated
19 in APE runs with those in the real atmosphere. However, we should be
20 cautious in such comparison for at least two reasons. First, behavior of at-

1 atmospheric disturbances depends on the surface boundary conditions, where
2 the APE and the real atmosphere differ considerably: the SST in the real
3 atmosphere is not zonally symmetric at all, whereas no land surface is as-
4 sumed in the experiments in the APE. Second, quantities observed in the
5 real atmosphere do not necessarily have temporal and/or spatial coverage,
6 resolution, and uniformity. The attempts of such comparison which follows,
7 therefore, inevitably remain superficial.

8 The wavenumber frequency spectra of OLR in the equatorial area has
9 been has been examined by a number of authors including Takayabu (1994a),
10 Wheeler and Kiladis (1999). Cho et al (2004) examine the precipitation data
11 from TRMM, and show that the type and character of CCEWs found in
12 the precipitation data is consistent with those in OLR data. In the annual
13 average of equatorially symmetric component, shown in Fig.3(b) of WK99,
14 that Kelvin and the equatorial Rossby signals are strong, and that weaker
15 but significant westward inertio gravity mode, whose dominant wavenum-
16 ber is larger than 4, and “TD-type” signal exist. WK99 also examines the
17 seasonal variation of the spectra. Their Fig.5(b)and(d) show significantly
18 different character of wave activity. TD-type signal is much stronger in
19 northern summer, whereas other types are stronger in southern summer.
20 The dominant wavenumber of the westward inertio gravity mode signal
21 varies seasonally, which is 2–7 in souther summer and is larger than 7 in

1 northern summer. Considering that the meridional distribution of SST pre-
2 scribed in the experiments analyzed in this paper is more similar to that of
3 southern summer rather than to that of northern summer, we would expect
4 weak AD component and strong K and WIG components. As was described
5 in Section 4, most model are, to some extent successful in reproducing K
6 component. Abundant presence of AD component in APE models might be
7 aganst the expectation above. However, the latitudinal distribution of AD
8 component in APE may differ from the “TD-type” signal in WK99; with the
9 sharp peak of SST in APE CONTROL (Fig. 1), convective activity in the
10 off-equatorial latitudes, which is one of the necessary ingredient of “TD” in
11 the real atmosphere, can not occur actively, and the AD component distur-
12 bance analyzed in this study may be different from the “TD-type” signal in
13 WK99. Instead, the AD component in this study may be related to “back-
14 ground” component in WK99. In APE, WIG signal appears clearly only
15 in a limited models; among the seven models that are intensively analyzed,
16 EC05, LASG, and GSFC represent appreciable WIG signal, and, NICAM
17 and K1JAPAN among the models not analyzed deeply. However, EC05
18 seems to be unsuscessful in presenting the WIG as a dominant signal along
19 dispersion curves of equatorial WIG mode. GSFC does not succeed in the
20 representation of long wavelength WIG component.

21 The spatial structure of CCEWs have been subject to a number of re-

1 search, such as Wheeler et al (2000), Yang et al (2007a,2007b,2007c) and
2 other studies reviewed by Kiladis et al (2009). It has been established that
3 Kelvin mode and westward inertio gravity mode have “boomerang” like
4 structure temperature anomaly, which can be interpreted as the internal
5 wave emitted upward and downward from the strong convective heating at
6 the updraft phase to the direction of propagation (Fig.7 in WK99 for Kelvin
7 mode, and Fig.23 for WIG mode). The contrast of humidity in the lower
8 troposphere, more humid before the convection and drier after, is another
9 important feature. Such structure is reproduced in only a small number of
10 models in APE analyzed here: EC05, EC07 and LASG are good in perfor-
11 mance in Kelvin component, and only LASG is good for WIG component.
12 The performance of NICAM in representation of Kelvin like structure, as is
13 extensively described in Nasuno et al (2008), seems to be quite successful,
14 but that for WIG is not known.

15 Horizontal structures of Kelvin and Rossby modes in the real atmosphere
16 are extracted and investigated by Yang et al (2007c), where the analysis are
17 conducted bearing the difference between the structures of waves on the
18 eastern and western hemispheres in mind. Comparing with Kelvin mode
19 structure in Fig.1 of Yang et al (2007c), we can find that the Kelvin mode in
20 the APE examined here is more similar to that in the western hemisphere,
21 noting the presence of significant meridional wind perturbation in the lower

1 troposphere and considerable rotational wind component in the upper tro-
2 posphere. Either of the structures of Rossby mode presented in Fig.5 for
3 the western hemisphere and Fig.9 for the eastern hemisphere of Yang et al
4 (2007c) is not similar to that of advective component in most of the APE
5 models presented here, in that those observed Rossby modes contains a pair
6 of distinct off-equatorial vortical cells in the lower troposphere. As is noted
7 earlier, such off-equatorial low level rotational signal can be noted only in
8 a small number of models (AGUforAPE and CSIRO); even in these mod-
9 els, the location of the maximum of vorticity is much nearer to the equator
10 compared with the those in Yang et al (2007c). The composite structure of
11 Kelvin and Rossby modes presented in Kiladis et al (2009) exhibit features
12 common to those in Yang et al (2007c). Finally, the horizontal structure of
13 WIG presented in Kiladis et al (2009) is generally in good agreement with
14 WIG in the present APE results.

15 The difference between the properties of their Rossby modes and the
16 present advective components may be quite natural considering the differ-
17 ence between the definition of the Rossby modes in those papers and that
18 of the “advective” component in this paper. Direct comparison requires ad-
19 ditional analysis focusing more sharply on the Rossby modes, which is left
20 for a future study. Another factors that may contribute to the difference in
21 all types of disturbances is the difference of meridional structure of SSTs in

1 the real atmosphere and the CONTROL profile of APE. In this respect, it
2 would be useful to compare the structure of convectively coupled equatorial
3 waves that appear in the APE experiments with the SST profiles other than
4 CONTROL, but it is left for future study, because complete re-run of the
5 models are indispensable in order to collect the necessary data.

6 It is interesting to note that, together with NICAM, which is with no
7 doubt one of the most advanced models, and LASG, which is equipped with
8 the simplest convective adjustment (Manabe et al. 1965), outperform most
9 other models with various kind of more complex cumulus schemes in several
10 aspects including the reproduction of the spectrum of WIG and the structure
11 of CCEWs. Of course, at least the former of the two may not be surprising
12 because most AGCMs are tuned to reproduce climatological states of the
13 atmosphere, so that WIG, which is short period and their relationship to the
14 long-time and/or large-scale atmospheric variables is unclear, has not been
15 subject to extensive tuning. The situation might have changed a lot since
16 the execution of APE, and more recent generation of models may perform
17 much better.

1 *6.3 Comparison with Convectively Coupled Equatorial Waves* 2 *represented in previous modeling studies*

3 Convectively coupled Kelvin mode has been investigated in several mod-
4 eling studies including those with the aqua planet setup (e.g., Frierson, 2007;
5 Lee et al, 2003) or those with realistic surface boundary condition (e.g., Lee
6 et al, 2003; Suzuki et al,2006; Frierson et al, 2010). These studies are aimed
7 at improvement of the representation of Kelvin modes with more or less
8 amount of “tuning” of the model. The structure of Kelvin modes simulated
9 in those studies, with successful performance in particular, shares several
10 aspects with observed waves such as the “boomerang” like structure tem-
11 perature. Compared with the similarity among those “successful” cases, the
12 structure of the Kelvin mode in APE experiments described in this paper
13 exhibits by far wider variety. Somewhat similar intercomparison is done on
14 Kelvin waves in CMIP3 (Coupled Model Intercomparison Project phase 3)
15 by Straub et al (2010). Although the comparison of the structure is, as
16 in the present paper, limited to a small number of models, considerable
17 diversity is found both in horizontal and in vertical structure, again as in
18 the present paper. All of these past and present results suggest that there
19 is much room for improvement of the representation of Kelvin modes.

20 Rossby mode, possibly corresponding to the advective component in
21 the present paper to some degree, and WIG mode have not investigated

1 so intensively with general circulation models. Suzuki et al (2006) exam-
2 ines Rossby modes focusing on the sensitivity to a modification of cumulus
3 parameterization. The horizontal structure of Rossby modes in their exper-
4 iments resembles no to those in the APE described in this paper but to that
5 of the observed waves (Kiladis et al. 2009), again suggesting the possible
6 importance of the choice of the SST profile noted earlier.

7 *6.4 Other branches in the frequency wavenumber space*

8 With different specification of SST profile, the space time structure of the
9 equatorial precipitation varies as is described in Blackburn et al (2011b).
10 Still, most of the features in the space time spectra can be classified as
11 Kelvin, advective and WIG signals as are described above. However, relative
12 power among the three types of signals varies reflecting the change of space
13 time structure of precipitation responding to the change of SST profile.
14 Here we mention only two of the notable features in experiment with the
15 SST profile other than CONTROL.

16 In FLAT experiment of ECMWF-07, not only n=1 WIG but also n=1
17 EIG signal can be distinctly appears. This may be understandable con-
18 sidering that the width of equatorial precipitation region is much broader
19 with the FLAT SST profile than with the CONTROL SST, so that the
20 EIG , which have more latitudinally extended region of convergence than

1 WIG, can interact with moist convection more easily. Actually, the power
2 of the EIG is found in the symmetric component of the precipitation in the
3 latitude band of 10-20 degree (not shown), which corresponds to the off-
4 equatorial peak of convergence in n=1 EIG, for example, see Fig.3 of Yang
5 et al (2003). However, the reason why n=1 EIG does not appear in other
6 FLAT experiment with models other than ECMWF-07 in spite that most
7 of them are characterized with equally broad ITCZ.

8 We mentioned the possible existence of the eastward propagating inertio
9 gravity waves also in CNTL of NCAR. We did not perform detailed anal-
10 ysis on the off equatorial structure, so that no firm conclusion is admitted
11 presently. It may worth noted, however, that the appearance of the eastward
12 gravity wave mode in CNTL of NCAR is consistent with that in FLAT of
13 ECMWF07; they are cases with double ITCZ or broad ITCZ, which allows
14 the coupling between the convective heating and the wave motion not only
15 at the equator but also that in off-equatorial latitude. Still, the coupling
16 may not be simple, because, in spite that ITCZ is broad or double in some
17 experiments other than CTCL of NCAR and FLAT of ECMWF07, east-
18 ward inertio gravity wave signal can not be identified in those models. To
19 solve these issues, further investigation is necessary with more augmented
20 datasets provided by re-run of models.

1 *6.5 Relationship between the height of convective heating and*
2 *phase speed of disturbance*

3 In all models, the vertical structure of convective heating in the three
4 spectral filtered composite are slightly different (Fig. 13, Fig. 20, Fig. 27).
5 If we compare them carefully, we can notice that, in each model, the “cen-
6 ter of gravity” of the convective heating is located at lowest level in WIG,
7 a little higher level in K, and at highest level in AD. Interestingly, the
8 above order follows the reverse of the phase velocity of the three compo-
9 nents relative to the low level zonal wind. In other words, if this is true,
10 the faster the intrinsic phase velocity of the disturbance, at the lower level
11 the convective heating occurs. Such tendency might be natural if one re-
12 calls that the development of (parameterized) moist convection requires
13 certain degree of moisture accumulation, for which certain length of time
14 would be necessary; if the wave period be shorter than the moisture ac-
15 cumulation time scale, the convective heating might be unable to respond.
16 This sensitivity of the heating to the period of disturbance is similar to,
17 but slightly different from, the idea of “phase lagged wave-CISK” proposed
18 by Davies (1979), or the effect of “convective response time” discussed by
19 several authors (e.g. Emanuel, 1993; Emanuel et al, 1994; Lindzen, 2003).
20 In phase-lagged wave-CISK, phase between the heating and the low level
21 upward motion is assumed to depend on the wave period, and in the formu-

1 lation in Emanuel(1993), the intensity of the heating is assumed to depend
2 on the wave period, whereas in the present analysis, the vertical structure of
3 the heating is shown to depends on the wave period. This is an interesting
4 possibility which could lead to another way of eliminating the “ultraviolet
5 catastrophe” from classical wave-CISK. However, before going further, how
6 such dependency emerge in the models should be investigated especially
7 because such intricate character on the interaction between convection and
8 large-scale motion is expected to be an difficult issue in the performance of
9 cumulus parameterization in general. This issue is left for future research.

10 **7. Concluding remarks**

11 We have examined the results of the Aqua Planet Experiment project
12 focusing mainly on the structure of equatorial precipitation in the subset of
13 participating models on which details of model variables are available. The
14 summary of results are presented in abstract so is not repeated here.

15 We can say that the simple and idealized setup of the APE project
16 has been quite successful in elucidating the similarity and difference of the
17 equatorial precipitation structure in different models. However, it is still dif-
18 ficult to explain what kind of differences in the choice of parameterizations
19 of physical processes are related to particular differences of the composite
20 structure. The source of difficulty is at least three-fold. First, the different

1 cumulus parameterizations contain different sets of internal variables and
2 the output variables, so that meaningful comparison among the behavior
3 of parameterizations is a difficult task. Second, partly due to the difficulty
4 noted above, we could not define appropriate datasets to describe the be-
5 havior of parameterizations of physical processes in advance, so that could
6 not obtain consistent datasets from the participating groups. Third, as is
7 almost always applies to the analysis of the atmospheric models, complex
8 entangled interplay among various dynamical and physical processes in the
9 models makes clear, simple interpretation impossible in spite of the simple
10 and unified external setup of Aqua Planet Experiments.

11 We can not be sure on to what extent the results of the present study
12 applies to the behavior of precipitation features in more realistic setup. This
13 is partly because we analyze only subset of CTRL experiments, which is,
14 in itself, a subset of the specifications in APE project. It should be bear
15 in mind that the CTRL case may not be most “realistic” setup among the
16 cases defined in APE project. For example, as described in Blackburn et
17 al (2011a), Ohfuchi et al (2011) and the APE-ATLAS (Williamson et al.
18 2011), the tropospheric jets in CTRL case are too strong and located at
19 lower latitude compared to the climatological zonal mean state of the real
20 atmosphere, and the ITCZ precipitation is, in most models, too much con-
21 centrated at the equator. The former point may affect the intensity and

1 character of the interaction between the tropics and mid-latitudes, and the
2 latter point may affect on many aspects of properties of convectively cou-
3 pled equatorial disturbances, i.e., the main results of this study. It is clear
4 that the present analysis should be supplemented by the analysis of other
5 cases, i.e., FLAT, QOBS and PEAKED cases. However, regrettably, the
6 composite analysis of those cases requires time series of three dimensional
7 model variables and tendency data that were not submitted on the most of
8 the participating models.

9 Lastly, we comment on the necessity of “APE2”, i.e., another execu-
10 tion of aqua planet experiment project. The numerical experiments for
11 the present APE by the participating groups were conducted in the period
12 of 2002–2007. Some of the results of this study, namely the large degree
13 of diversity found in the properties of precipitation such as the intensity
14 of Kelvin, gravity, and advective components and the vertical structure
15 of the composite structure of the three, may originate from immaturity
16 of the atmospheric models in that period. The same can be said about
17 other diversity found among the different models described in APE-ATLAS
18 and Blackburn et al (2011ab). Because global atmospheric models have
19 been developing extensively in many aspects such as spatial resolution and
20 the parameterizations, it is worth repeating the Aqua Planet Experiment
21 project in a basically the same framework. It is particularly interesting to

1 examine whether the current generation of atmospheric models will still ex-
2 hibit diversity like shown in this paper or not. In the possible repetition
3 of APE, it should be important to collect more complete datasets on all of
4 the cases; the time series of low level atmosphere would be indispensable to
5 examine the tropical disturbances. Finally, it should be stressed that, not
6 only to compare but also to interpret the results of experiments, complete
7 enough description of numerical models is indispensable. It would be ideal
8 that every participating group would provide the source code of the numer-
9 ical model used and interested members can re-run models of other groups.
10 Such deep collaboration may not be so easy, but would be very fruitful to
11 advancement of modeling community.

12 **Acknowledgements**

13 The authors thank the APE participants of CSIRO, ECMWF, GSFC,
14 LASG, and, NCAR for providing the additional transient data used in this
15 study. Numerical integration of AGU model were performed at the Earth
16 Simulator Center. Analysis software and local computational environments
17 were constructed by the use of the resources of GFD-DENNOU-CLUB
18 (<http://www.gfd-dennou.org>), including GPhys (<http://ruby.gfd-dennou.org>),
19 spmodel (<http://www.gfd-dennou.org/library/spmodel>), and DCL ([http://www.gfd-](http://www.gfd-dennou.org/library/dcl)
20 [dennou.org/library/dcl](http://www.gfd-dennou.org/library/dcl)). This work was supported by Grants-in-Aid(B) for

1 Scientific Research (12440123 and 21340139).
